

1 Chapter 11

2 **Approaching Color with**
 3 **Bayesian Algorithms**

4 Sarah Allred

5 What is the goal of color vision? How ought we to think of color appearance? Under one
 6 view, the goal of vision is to maintain a stable representation of object properties across
 7 changes in the environment. This poses a challenge to the visual system, because the sen-
 8 sory signal on which visual perception is based is ambiguous with respect to the physical
 9 properties of objects in the world. Thus, to maintain stable color appearance, the visual
 10 system must estimate what object was most likely to have caused the ambiguous sensory
 11 signal (Helmholtz 1910/1924). In this chapter, I present a Bayesian approach to solving
 12 this estimation problem that relies on statistical regularities in the world to resolve the
 13 sensory ambiguity. This is a sensible idea: the human visual system evolved in this world,
 14 and thus its statistical regularities are likely to be of functional importance to vision
 15 (Attneave 1954; Geisler and Kersten 2002; Mamassian et al. 2002; Weiss et al. 2002).

16 Any functional understanding of vision has to deal with the problem of information
 17 loss between the distal object and its visual representation. In color vision, there are sev-
 18 eral salient sources of information loss. First, there is ambiguity inherent in image forma-
 19 tion, illustrated in Figure 11.1. In color vision, that ambiguity takes the form that the light
 20 reaching the eye from a surface j [$C_j(\lambda)$, sensory signal] confounds reflectance properties
 21 of the surface [$S_j(\lambda)$] with the properties of the illuminant [$E_j(\lambda)$]. Color perception
 22 typically follows the properties of a surface rather than the illuminant. However, the sen-
 23 sory signal that gives rise to color perception is ambiguous with respect to which surface
 24 gave rise to it; that is, infinitely many combinations of surfaces and illuminants could
 25 have caused any given sensory signal. Despite this ambiguity in the sensory signal, our
 26 perception is (usually) not ambiguous; that is, at any given time, we only perceive one
 27 color at a particular spatial location.

28 A second kind of information loss occurs because of the physiological properties of the
 29 photoreceptors. As illustrated in Figure 11.1, under normal light levels, human vision
 30 relies upon three different photoreceptor classes, L-, M-, and S-cones. Each cone type
 31 is most sensitive to a different wavelength of light; color vision relies on the comparison
 32 of the responses of these three cone types to a given sensory signal. Thus, rather than
 33 representing the intensity of each wavelength in the sensory signal, the photoreceptors
 34 can be characterized as giving three discrete intensity values (r_j). Despite this trichro-
 35 matic representation of a continuous color spectrum at the earliest level of the physiology,
 36 a continuous color circle still captures many aspects of color experience.

Fig. 11.1 Illustration of sensory ambiguity. (© Maria Olkkonen, 2011, reproduced here with permission.) (See also Plate 10.)

1 Third, information loss occurs because of noise in the physiological system.
 2 Photoreceptors signal the presence of light to subsequent parts of the visual system
 3 through a change in electrical current flowing through the photoreceptor; that change is
 4 mediated by photopigment isomerization. When a photopigment absorbs light, its shape
 5 changes. This change in shape initiates a cascade of events that eventually alters the
 6 amount of neurotransmitter released by the photoreceptor, which in turn affects the
 7 responses of other neurons in the visual system. However, the responses of photorecep-
 8 tors are noisy; that is, subsequently presented identical stimuli can cause different num-
 9 bers of photopigment isomerizations. In addition, sometimes photopigments isomerize
 10 in the absence of light. In high-light conditions, photopigment isomerizations are domi-
 11 nated by the light incident on the photoreceptors; however, at low illumination levels,
 12 isomerizations due to chance may be closer in magnitude to the response evoked by a
 13 visual stimulus. Particularly at low-light levels, photoreceptor noise can have interesting
 14 perceptual effects.

15 **To perceive, one must guess**

16 Although the ambiguities described here are particular to color perception, sensory ambi-
 17 guity is fundamental to all visual perception. For any visual property (e.g., color, size,
 18 shape, distance, depth, gloss), reconstruction of the distal stimulus from the sensory sig-
 19 nal is an underdetermined problem. In other words, there is no theoretical way to recov-
 20 er the distal stimulus from the sensory signal without applying some sort of guessing rule,
 21 heuristic, or external constraint. Although some descriptions of visual processing leave
 22 these guessing rules unstated, any explanation of visual perception tied to a reconstruc-
 23 tion of the distal stimulus requires guessing rules. These rules may be stated or unstated,

1 formulated implicitly or explicitly, described functionally or mechanistically, and imple-
 2 mented qualitatively or quantitatively, but they are necessary for a complete characteriza-
 3 tion of visual perception. To perceive, one must guess. Moreover, one set of guessing
 4 rules is not enough; visual constancy (or the ability to perceive an object the same way
 5 in different environments) requires that guessing rules change from environment to
 6 environment.¹

7 How ought the visual system to deal with this information loss? Given that the visual
 8 system must guess, how ought it to guess best? There are a number of possible answers.
 9 In this chapter, I describe a Bayesian computational approach to formulating these guess-
 10 ing rules. To motivate the description and evaluation of the Bayesian approach, I first
 11 outline some perennial problems of visual perception. Second, I outline the general prin-
 12 ciples of Bayesian algorithms. Importantly, the Bayesian approach to visual perception as
 13 described here does not aim for veridicality per se; rather, it aims to describe human per-
 14 ception. Third, I illustrate the utility of the Bayesian approach to two specific cases, color
 15 constancy and color appearance. Finally, I compare and contrast the Bayesian approach
 16 to other ways of describing visual perception and I discuss the empirical, theoretical and
 17 philosophical advantages that accrue from a Bayesian approach.

18 The puzzle of constancy

19 As already outlined, the ambiguity in the sensory signal makes unambiguous perception
 20 a computational puzzle. However, visual constancy also raises a number of philosophical
 21 puzzles. For example, consider naïve realism. This is the idea that humans perceive
 22 directly the properties of objects in the world. Naïve realism says that perception of an
 23 object's color and size should remain constant across changes in that object's environ-
 24 ment. After all, what has changed is the environment, not the object (or its properties).
 25 A banana seen on a green banana plant outdoors should appear to have the same color as
 26 a banana under the fluorescent light of a grocery store. A newspaper under partial shadow
 27 should appear to have uniform color. If naïve realism were correct—or, in other words,
 28 if it were true that humans had complete visual constancy because they directly perceive
 29 object properties themselves—visual constancy would be a computational puzzle but not
 30 a philosophical one.

31 However, a first philosophical puzzle arises from noting that humans demonstrably do
 32 not achieve complete visual constancy. In the case of color, empirical studies suggest that
 33 color constancy in relatively realistic environments is around 60% (see Shevell and

¹ As an example, consider the “guessing rule” of using local contrast rather than luminance to encode surface lightness of an object. Then consider two changes to the visual environment. In A, the illumination changes; for example, the intensity of the light source in the room is increased. In B, the illumination stays the same, but the object is placed on a darker surface, one with lower reflectance. Contrast coding would support lightness constancy in A, since the luminance ratio between the object and its surround has not changed. However, in B, application of contrast coding would make appearance invariant; the object would appear lighter because the luminance ratio between the object and its surround has increased.

1 Kingdom 2008 for review). Furthermore, the degree to which humans (and animals)
 2 exhibit color constancy is highly dependent on the environment. Variables that affect the
 3 degree of color constancy between environments include the complexity of the environ-
 4 ment (Fleming et al. 2003; Kraft et al. 2002; Schirillo 1999), scene geometry (Allred and
 5 Brainard 2009; Boyaci et al. 2003; Schirillo et al. 1990), material properties such as gloss
 6 (Xiao and Brainard 2008), and whether the environmental changes are in the illumina-
 7 tion or in the surrounding surfaces (Allred and Brainard 2009; Arend and Spehar 1993a,
 8 b; Kraft and Brainard 1999; Delahunt and Brainard 2004). Why does the visual system
 9 have incomplete constancy? And why is it so variable?

10 The puzzle of incomplete constancy is exacerbated by the fact that there are conditions
 11 under which individuals can make multiple perceptual judgments about the same stimu-
 12 lus. The possibility of multiple judgments is clear through introspection, and is verified
 13 by empirical studies (Arend and Spehar 1993b; Blakeslee et al. 2008). For example, when
 14 one looks at a surface like a book under a sharp shadow, there is a sense in which it is clear
 15 that the cover of the book is all the same color, but there is also a sense in which the part
 16 of the book under shadow seems darker. Thus, multiple judgments are made: the color of
 17 the book looks to be the same and also appears to vary. A silver dollar seen at an angle can
 18 be judged both as elliptical and as circular. A large object (like a car) seen at a distance is
 19 experienced both as being large and as being smaller than it is when it is viewed up close.

20 That multiple judgments about the same stimulus can be made under some conditions
 21 is clear, both from introspection and from empirical studies. Less clear is the characteri-
 22 zation of when multiple judgments can be made—are there only certain circumstances
 23 when this can happen, or is it always possible? Consider again the book under shadow.
 24 Are there some shadows under which the book appears only one color? Are there some
 25 distances or objects for which the object looks exactly the same despite changes in its
 26 distance or orientation? The literature is murky on this point. Particularly in the cases of
 27 color, there are times when it seems only one judgment can be made; that is, even when
 28 observers are instructed to make multiple judgments, they can make only one (Arend and
 29 Spehar, 1993a; Ripamonti et al. 2004). However, there are also circumstances in which
 30 observers can comfortably make multiple judgments (Arend and Spehar 1993b; Blakeslee
 31 et al. 2008). Why should it be the case that multiple judgments are sometimes, but not
 32 always, possible? Is it possible to predict the circumstances under which multiple judg-
 33 ments are possible?

34 As outlined from both computational and perceptual perspectives, the puzzles of con-
 35 stancy are threefold. First, given the ambiguity in the sensory signal, how ought the visu-
 36 al system to arrive at an unambiguous percept? Second, is there a principled way to
 37 predict when that ambiguity will be resolved veridically? That is, is there a principled way
 38 to predict the extent to which humans achieve color constancy in different environments?
 39 Finally, is there a principled way to predict the circumstances under which multiple judg-
 40 ments of color appearance can be made; and, when multiple judgments can be made, can
 41 one assert whether a given judgment is perceptual or cognitive? In the following sections,
 42 I describe an answer to these questions that relies on Bayesian statistical theory. In the
 43 end, I argue that using a Bayesian approach facilitates answers to the first two questions

1 by providing a quantitative account of empirical data. I also argue that the success with
 2 which Bayesian algorithms resolve sensory ambiguity and predict variable constancy
 3 points to several ways one might think about answering the latter question of multiple
 4 judgments. To do so, I first describe the general principles of Bayesian algorithms.

5 **General principles of Bayesian algorithms**

6 Any Bayesian algorithm makes an optimal interpretation of some set of data. Here
 7 Bayesian algorithms are applied to the problem of color: the optimal interpretation is a
 8 judgment about color and the data are some parameterization of a sensory stimulus (e.g.,
 9 values for the isomerization rates of different photopigments in response to incident light
 10 reflected from a colored surface). Importantly, as described here, the Bayesian approach
 11 aims to predict human perception rather than veridicality per se. In this sense, the
 12 Bayesian approach to color perception is distinct from many other computational
 13 approaches. Many computational approaches aim for veridicality (either implicitly or
 14 explicitly); that is, they aim to recover accurately the distal object from the sensory signal
 15 (Retinex is an example, see Land and McCann 1971). However, as we will see, the Bayesian
 16 framework is absent the notion that optimality requires veridicality. As formulated spe-
 17 cifically in the context of color perception, we can think of a Bayesian algorithm as guess-
 18 ing what state of the world (the *optimal* interpretation, as explained below) caused the
 19 sensory signal that reaches the eyes (the data). Keep in mind, however, that this optimal
 20 guess may not be the one that correctly describes the physical properties of the stimulus.

21 To illustrate the process by which the Bayesian algorithm makes this guess, consider the
 22 following simple example. Suppose the world consists of a single object comprised of a
 23 single surface that reflects only one wavelength of light. In this scenario, which wave-
 24 length is reflected can be ignored, but the percentage of light reflected (surface reflect-
 25 ance) is the relevant characteristic of the state of the world, and one that can vary from
 26 surface to surface. The datum from which the algorithm must guess this object's surface
 27 reflectance is a single value, the intensity of light that reaches the eye. As illustrated in
 28 Figure 11.1, the intensity of light reaching the eye (the datum) is a product of the reflect-
 29 ance of the surface and the light that is available to be reflected (the illuminant). The
 30 Bayesian algorithm must take the single datum (the intensity value) and make its best
 31 guess about the state of the world (the reflectance of the object and the intensity of the
 32 illumination) that caused the datum. In other words, the Bayesian algorithm must take
 33 one value (intensity) and guess two values (surface reflectance, illumination). Now sup-
 34 pose, in this single surface world, that illumination changes while the reflectance of the
 35 object stays the same. This would change the datum (the intensity of the light reaching
 36 the eye). If the algorithm predicts the reflectance to be the same in both illumination
 37 contexts, then the algorithm predicts constancy; if, on the other hand, the algorithm pre-
 38 dicts different reflectance values in the two illumination contexts, then the algorithm
 39 shows a failure of constancy.

40 How do Bayesian algorithms arrive at an optimal interpretation of the data? First, the
 41 algorithm computes the probability of each possible state of the world conditional on the

1 data at hand. In the one-surface world, this is every combination of reflectance and illu-
 2 minant (state of the world) that could have caused the observed intensity of light (datum).
 3 For example, one possible state of the world is a high illuminant and low surface reflect-
 4 ance, another possible state of the world is a low illuminant and a high surface reflectance.
 5 This probability distribution—the probability of each possible state of the world given
 6 the data—is called the posterior distribution.

7 This posterior distribution is generated by multiplying two other probability distribu-
 8 tions—the *likelihood* and the *prior*. The *likelihood* is the probability that the datum would
 9 be observed given each possible state of the world. For example, suppose my datum is 10
 10 units. How likely is a sensory signal of 10 units if the state of the world is a reflectance of
 11 0.1 and an illuminant of 100? The value is calculated using a likelihood function; concep-
 12 tually, the likelihood function captures both sensory noise and the ambiguity inherent in
 13 image formation. In the one-surface world, for example, likelihood values will be high for
 14 states of the world that are consistent with the data (e.g., reflectance of 0.1 and illuminant
 15 of 100, or reflectance of 1 and illuminant of 10) and low for states of the world that are
 16 inconsistent with the data (e.g., a reflectance of 1 and an illuminant of 10,000, or a reflect-
 17 ance of 0.01 and an illuminant of 1). The exact value of the likelihood depends on the
 18 sensory noise. If there were no sensory noise (for example, if photoreceptors responded
 19 exactly the same every time they were stimulated by a given number of photons), only
 20 states of the world perfectly consistent with the datum would have a non-zero likelihood.
 21 Furthermore, all consistent states of the world would have equal likelihood. In contrast,
 22 large sensory noise permits higher likelihood values for reflectance-illumination combi-
 23 nations that are not consistent with the data. The precise formulation of the likelihood
 24 varies with the complexity of the algorithm, but for color perception, likelihood functions
 25 might utilize information about phototransduction noise, cone isomerization rates, or
 26 cone metamerism. Importantly, there are often multiple states of the world with identical
 27 likelihood values; this is another way of saying that the data alone are ambiguous with
 28 respect to what object(s) caused them.

29 The *prior* is the probability that any given state of the world exists to begin with, inde-
 30 pendent of the data. This part of the Bayesian algorithm captures information we have
 31 about the statistics of the world. In our one-surface world, the prior would contain two
 32 one-dimensional probability distributions, one for surface reflectance and one for illumi-
 33 nants. If there were more dark surfaces than light surfaces in the world, for example, the
 34 prior probability for surfaces with low reflectance would be greater than the prior prob-
 35 ability for surfaces with high reflectance. Intuitively, the prior can be thought of as the
 36 guessing rules to resolve the sensory ambiguity of the likelihood. Next, the posterior
 37 probability—the probability of each possible state of the world, given the data—is com-
 38 puted by multiplying the likelihood of each state of the world by the prior probability of
 39 each state of the world.²

² The exact values of the likelihood and prior depend on their specific characterization; this is often a statistical distribution with a known probability density function. In principle, values are normalized

1 The final step in making an optimal estimation is to convolve the posterior distribution
 2 with a loss function, sometimes called a cost function or utility function. This function
 3 describes the cost associated with incorrectly estimating any particular state of the world.
 4 In the one-surface world, for example, if there were a high cost for guessing that a surface
 5 was very white when it was actually closer to black, the cost function would shift the opti-
 6 mal estimate towards a darker surface than the posterior distribution alone would yield.
 7 Intuitively, the loss function captures information about task strategy. The convolution
 8 of the posterior distribution with the loss function yields the expected Bayes' utility. The
 9 optimal interpretation of the data (in the one-surface world, the algorithm's final guess
 10 about reflectance and illuminant) is the state of the world with the highest expected
 11 Bayes' utility. Many Bayesian models, including all of those presented in this paper, have
 12 a simple, uniform loss function, and thus the optimal interpretation is driven entirely by
 13 the posterior. However, strategic effects can be modeled using the loss function.

14 **A Bayesian model of color constancy**

15 To illustrate the value of the Bayesian approach, consider the case of color constancy. For
 16 the color appearance of an object to be useful, it should be approximately constant; that
 17 is, it should correlate with reflectance properties of that object across changes in the envi-
 18 ronment. Such changes could include the intensity and chromaticity of the incident illu-
 19 mination and the reflectance properties of surrounding objects. As discussed previously,
 20 the human visual system is approximately color constant, but it has been difficult to
 21 predict the extent of that constancy in different environments. Recently, Brainard and
 22 colleagues (2006) proposed a Bayesian model of color constancy that provided a good
 23 explanation for the color appearance of surfaces under different illuminants. This model
 24 predicted both successes and failures of color constancy. An overview of the model is
 25 presented here; for detailed information, see Brainard et al. (2006).

26 To understand the model, recall that any Bayesian algorithm estimates what state of the
 27 world most likely caused a particular set of data. For the color constancy algorithm, the
 28 "state of the world" is characterized as a mathematical approximation of the reflectance
 29 of a series of surfaces and the chromaticity of one uniform illumination. The data are
 30 conceived as the isomerization rates of the three photoreceptor types. The likelihood
 31 function then captures the mapping between states of the world (surfaces/illuminant)
 32 and the data (isomerization rates). This mapping took the form of modeling the sensory
 33 signal as the multiplication of the surface reflectance vectors by the illuminant chromatic-
 34 ity, using a biological model of the absorption spectra of the different photoreceptor
 35 classes to estimate average isomerization rates, and then perturbing those isomerization
 36 rates with noise (see Brainard et al. 2006 for the mathematics). The likelihood function
 37 characterizes the probability with which any combination of reflectance and illuminants
 38 would have caused the modeled isomerization rates of the cone classes. Intuitively, this

.....
 by a constant. In practice, we are often more interested in knowing relative probabilities than absolute
 probabilities, and the constant is ignored.

1 likelihood function captures knowledge of image formation and early sensory processing
2 of the cones.

3 As in the one-surface world, however, multiple combinations of reflectance and illumi-
4 nant are equally consistent with the data. To make an optimal estimate or guess, the
5 algorithm uses the prior; that is, the probability with which any particular reflectance or
6 illuminant is likely to occur in the first place. To create the prior for surfaces, Brainard
7 et al. (2006) first assumed that surface reflectance functions are well approximated by a
8 three-dimensional linear model. This assumption is frequently used in rendering applica-
9 tions (e.g., 3D computer graphics in video games or movies). The basis functions for the
10 linear model were obtained via statistical methods from empirically measured surface
11 reflectance functions. The same process was repeated to characterize illuminant spectral
12 power functions. The average chromaticity of the illuminant prior was set as the CIE
13 illuminant D65.³ The remaining parameters determining the relative probability of other
14 chromaticities compared to the mean were estimated from a set of measured daylight
15 spectra. There are several steps of mathematical simplification, but these priors capture
16 the intuition that the visual system expects a distribution of illuminants that occurs under
17 various daylight conditions, and it expects surface reflectances that are likely to occur in
18 the natural world.

19 To get the posterior distribution, the prior is multiplied by the likelihood, and the esti-
20 mate of scene illuminant and reflectance of the surfaces within the scene is the maximum
21 of the posterior distribution. Thus, for any arbitrary scene, the algorithm can estimate the
22 illuminant and reflectance of surfaces within the scene.

23 The computational challenges involved in arriving at an unambiguous prediction of
24 reflectance and illuminant chromaticity are non-trivial. However, the fact that an algo-
25 rithm can pick one interpretation out of an infinite number is not sufficient to recom-
26 mend the algorithm; the chosen interpretation should be sensible. To evaluate the success
27 of the algorithm, it is important to compare its predictions to human judgments of color
28 appearance. To do so, Brainard et al. (2006) compared model predictions to data col-
29 lected by Delahunt and Brainard (2004). In that experiment, observers successively
30 viewed seventeen simulated scenes (see Fig. 11.2) and adjusted a test spot within the scene
31 until it appeared achromatic (that is, lacking in color, except for white, gray, or black).
32 The background reflectance and the illuminant were both varied between scenes. In gen-
33 eral, Delahunt and Brainard (2004) reported much higher degrees of color constancy
34 when the illuminant alone was varied than when both the illuminant and the background
35 reflectance were varied.

36 Any comparison of algorithm estimates to human perception involves an explicit link-
37 ing hypothesis; that is, it requires a way to relate algorithm estimates of scene parameters

³ This is considered a “standard daylight illuminant”; purchasers of light bulbs aimed at full-spectrum or daylight illumination may see this notation on their packaging. Please note: in the text “CIE” stands for Commission Internationale de l’Éclairage.

Fig. 11.2 Examples of four stimulus configurations viewed by human observers in Delahunt and Brainard (2004). Subjects adjusted a test patch at the location indicated by the black square until it appeared achromatic. (Reproduced from Brainard, David H., David R. Williams, and Heidi Hofer, Trichromatic reconstruction from the interleaved cone mosaic: Bayesian model and the color appearance of small spots, *Journal of Vision* 8(5): pp. 11–23 © 2008 Association for Research in Vision and Ophthalmology, with permission.) (See also Plate 11.)

1 to human estimates of color perception. Here I discuss model estimates of illuminant
2 reflectance and illuminant chromaticity estimated from human achromatic settings.⁴

3 Model estimates of illuminant intensity tended to agree well with those inferred from
4 human observers' achromatic points. Interestingly, the model's failures to predict veridi-
5 cal illuminant intensity were often accompanied by failures of human color constancy.
6 There are an infinite number of combinations of surface reflectance and illuminants that
7 could give rise to the sensory signal as modeled in the paper. On average, the algorithm
8 predicted illuminant chromaticity correctly in the same contexts that elicited veridical
9 judgments of illuminant chromaticity from human observers.

10 One of the puzzles outlined above is the variability of color constancy in different envi-
11 ronments. Here the Bayesian algorithm predicts that variability. Interestingly, the way it
12 does so provides some insight. The algorithm predicts failures of constancy in contexts
13 where the illumination profile is relatively improbable according to the prior distribu-
14 tion. One experimental example is an environment with purple illumination. According
15 to the prior, purple illumination is very improbable. When a "purple" sensory signal is

⁴ The measure of constancy in these experiments is complicated and illustrates the philosophical issues at hand. Constancy implies that an achromatic surface will continue to appear achromatic under different illuminations. Constancy indices typically reflect the degree to which experimental settings conform to that actual achromatic surface. However, there is no principled reason to stipulate the illumination under which achromatic settings reflect "real" achromatic reflectance properties. To increase the chances that any reported failures of constancy were not simply failures to characterize the "real" achromatic surface, Brainard et al. used numerical search to infer the reflectance properties of an achromatic surface that minimized the constancy errors across all 17 contexts simultaneously. Although observers actually adjusted knobs until the light reaching their eyes appeared achromatic, this process of inferring the reflectance properties of an achromatic surface allows characterization of the human observers' estimates of the illuminant chromaticity. The algorithm estimates illuminant chromaticity. Achromatic settings in different contexts can be predicted from these estimated illuminant chromaticities. The differences between actual and predicted achromatic chromaticities are the data plotted in Brainard et al. (2006). This analysis is complicated. For simplicity and because estimates of illuminant chromaticity are at the heart of both model and human calculations, I refer to model and human comparisons of illuminant chromaticity rather than predicted and actual achromatic characteristics.

1 encountered, therefore, odds are that the “purpleness” arose from a purple surface rather
 2 than a purple light. The prior quantitatively implements that probability. Because of this,
 3 the Bayesian algorithm predicts relatively low constancy for purple illumination; that is,
 4 it predicts that observers will interpret surfaces under a purple light as being more purple
 5 than they really are. This prediction agrees with observer estimates. Thus, the Bayesian
 6 algorithm suggests that observers will exhibit low degrees of constancy when the actual
 7 state of the world is an improbable one.

8 To summarize, the Bayesian model of color constancy does four things. First, the
 9 model solves the computational puzzle of arriving at one estimate of color from the infi-
 10 nite number of possibilities presented by the sensory signal. Second, the solutions at
 11 which the model arrives predict human perception well. Third, the model predicts the
 12 variability in human color constancy. Finally, the model provides a principled reason for
 13 that variability; that is, constancy is worse when the visual system encounters relatively
 14 improbable events.

15 **A Bayesian model of color appearance**

16 There are a number of unresolved issues surrounding the mapping between the color
 17 appearance of stimuli and the physiological responses early in the visual system to those
 18 stimuli. One example is the way in which the retinal photoreceptor tiling in an individual
 19 is related to that individual’s phenomenal color experience. For example, it is an empiri-
 20 cal observation that the ratio of L to M cones varies substantially between subjects, as does
 21 the pattern in which they are arranged (Hofer et al. 2005a, b). The ratio also varies by
 22 location in the retina even with individual subjects. The comparison of different cone
 23 classes is necessary for color vision. If color appearance at a particular retinal location is
 24 dependent on the comparison of L and M cone responses in that location, then this inter-
 25 and intra-subject variability raises the perplexing question of how color appearance is
 26 relatively stable across retinal location and between observers (see MacLeod 2010 for
 27 discussion).

28 How should the variability in photoreceptor mosaic affect the color appearance in an
 29 ideal observer? Brainard et al. (2008) took advantage of recent advances in the experi-
 30 mental technique of adaptive optics to address this question. Adaptive optics has made
 31 it possible to present very small spots of light to the retina of awake, behaving human
 32 observers. These spots are so small and well characterized that there is a high probability
 33 that a single stimulus falls on a single cone. Further, extensive imaging of individual
 34 human retinas has made it possible to estimate the photoreceptor tiling in individual
 35 observers. These techniques are complicated and explaining them is beyond the scope of
 36 this chapter (see Hofer et al. 2005a for discussion). Here the results are summarized.

37 Hofer et al. (2005a) presented monochromatic stimuli to observers after imaging their
 38 photoreceptor mosaics. Examples of differences between photoreceptor mosaics are
 39 shown in Figure 11.3, where the variation is qualitatively obvious. For example, observer
 40 HS had primarily M-cones (colored green), while observer BS had primarily L-cones
 41 (colored red).

Fig. 11.3 Illustration of a small part of the photoreceptor mosaic for five subjects. Retinas were imaged using adaptive optics techniques described in Hofer et al. (2005a). Williams, and Heidi Hofer, Trichromatic reconstruction from the interleaved cone mosaic: Bayesian model and the color appearance of small spots, *Journal of Vision* 8(5): pp. 11–23 © 2008 Association for Research in Vision and Ophthalmology, with permission.) (See also Plate 12.)

1 After the flashes were presented, observers reported the apparent color of any flashes
 2 that were sensed. Not all flashes were detected. Hofer et al. (2005a) observed both intra-
 3 observer and inter-observer variability in reported color. For example, the retinal loca-
 4 tion of the presented stimulus affected the response of individual observers, such that the
 5 same stimulus could be named a different color depending on where in the retina it was
 6 presented. Figure 11.4 (left panel) shows the variability in color names for a 550-nm light.
 7 Monochromatic 550-nm light presented under normal conditions is named green, yet
 8 under conditions that stimulated a single cone, observers gave up to nine different color
 9 names to the same physical stimulus. Moreover, the relative frequency of different color
 10 names varied between observers. An example of this variability is seen in Figure 11.4,
 11 where observer YY used blue much more frequently than did observer BS, though they
 12 both “saw” the same 550-nm stimulus.

13 What can account for this pattern of results? To further understand the complexity of
 14 the pattern, first consider that although the portions of the retina imaged contained some
 15 S-cones, 550-nm light does not elicit responses from S-cones. Thus, it is likely that at
 16 most two different physiological responses (either M- or L-cone) elicited the full range of
 17 color names. Second, a salient feature of the data is that a number of stimuli were report-
 18 ed as achromatic (see Fig. 11.4, top panel), although every stimulus was monochromatic
 19 and stimulated only one cone. The traditional view in color science is that stimuli appear
 20 achromatic when all three cone classes are stimulated equally. Taken together, as Hofer
 21 et al. noted (2005a), these results show that stimulating a single cone type resulted in phe-
 22 nomenally different experiences. This provides a challenge for theories of color appear-
 23 ance that equate stimulation of a particular cone class with an elemental sensation.

24 Comparing the individual photoreceptor mosaics and the color names (Fig. 11.3 and
 25 Fig. 11.4) does not present an immediately obvious explanation for the results. To account
 26 for the results, Brainard et al. (2008) formulated the color naming task as the output of a
 27 Bayesian model that estimated the most likely color from a noisy photoreceptor array.

28 To understand this Bayesian algorithm, consider again the process of computing the
 29 optimal interpretation (chromaticity of the stimulus, mapped to a color name) from a set

1 of data (in this case, the expected mean isomerization rates of the cones in each individ-
 2 ual's retina after accounting for the expected blur due to the optics of the eye). The
 3 known features of the retina and physiological properties of different photoreceptors
 4 were used to model the likelihood. As with the color constancy model, the key feature of
 5 the model is the prior. The prior here incorporates several observations about natural
 6 images. First, the intensity in images tends to vary slowly over space. Second, the isomer-
 7 ization rates of L-, M-, and S-cones at a given location tend to be highly correlated. This
 8 occurs both because of the properties of images and the properties of the cones them-
 9 selves. The math required to implement these ideas is complicated, but the essence is that
 10 the prior incorporates intuitions about correlations across space and color.

11 The Bayesian algorithm then estimated the most likely ideal image given the photore-
 12 ceptor responses. To convert the algorithm output to a form that could be directly com-
 13 pared with psychophysical observations, Brainard et al. (2008) used a standard map of
 14 chromaticity to color names. The model estimates are shown in Figure 11.4 (right panel).
 15 The model predicted the variability between subjects both in terms of the colors named
 16 and the proportion of colors called achromatic.

17 In this case, a new experimental technique (adaptive optics) revealed situations in which
 18 our intuitions about color appearance are incorrect; the appearance of small spots is *not*
 19 constant across retinal location within an observer, and the appearance of small spots is *not*
 20 constant across observers. The Bayesian model that estimates the most likely ideal image
 21 from expected isomerization rates of cones is in agreement with the empirical data.

22 At first glance, it may seem surprising that intuitions about color appearance are so
 23 wrong; why do we believe color appearance to be stable across retinal position if it is not?

Fig. 11.4 Actual (left) and predicted (right) color names for presentation of 550-nm spots. The observers' task was to report the color of each spot they judged nameable. The histogram shows the proportion of total presentations named the illustrated color. (Reproduced from Brainard, David H., David R. Williams, and Heidi Hofer, Trichromatic reconstruction from the interleaved cone mosaic: Bayesian model and the color appearance of small spots, *Journal of Vision* 8(5): pp. 11–23 © 2008 Association for Research in Vision and Ophthalmology, with permission.) (See also Plate 13.)

1 The answer lies again with probability. Spots of light this small are very unlikely. They are
 2 so unlikely, in fact, that they would never have been encountered over the course of our
 3 evolutionary history. Although the priors in this algorithm were designed using the sta-
 4 tistics of common natural images, here they are used to predict the appearance of very
 5 unlikely stimuli. A good test of a model is whether it can generalize to predict the appear-
 6 ance of novel stimuli; in this case, Brainard et al. (2008) simulated the cone responses
 7 to more typical, larger stimuli. The same model that predicted variability in color appear-
 8 ance to “unlikely,” highly localized, monochromatic stimuli revealed stability of color
 9 appearance across less localized stimuli. For example, the ideal images for simulated
 10 isomerization rates of cones to larger spots of uniform color, or to low-frequency sinuso-
 11 dal color gratings (wide stripes of color) were stable across subjects and close to veridical.
 12 To summarize, the Bayesian model of color appearance of very small spots also address-
 13 es the puzzles described in the introduction. First, it solves the computational problem of
 14 arriving at a single prediction of color from an ambiguous sensory signal, in this case the
 15 isomerization of a single cone. Second, the color names chosen as optimal by the model
 16 are in agreement with the color names utilized by human observers. Third, this algorithm
 17 also predicts the inter- and intra-observer variability in color names. Fourth, as with the
 18 previous model, the way in which the model predicts this variability provides useful
 19 information. In order to predict the variability, the model assumes that the visual system
 20 is attempting to guess what stimulus was in the world. There is always ambiguity in the
 21 sensory stimulus. The model assumes that the visual system applies the same priors
 22 (guessing rules) to judging the appearance of very small spots as it would apply to judging
 23 the appearance of larger, more typical stimuli. In other words, the prior says that highly
 24 localized stimulation of a single cone is very, very unlikely. When it receives sensory input
 25 consistent with a single cone being stimulated, the visual system will guess that parts of
 26 the sensory signal were due to noise. The visual system will guess (because of the priors)
 27 that the stimulus presented was larger and more chromatically correlated than it actually
 28 was. An important test is that the priors that predict the appearance of very small spots
 29 also predict the veridical appearance of more typical stimuli. Thus, the priors that predict
 30 the appearance of small spots tell us something about the guessing rules that humans
 31 employ under more normal viewing conditions; they provide a principled explanation
 32 for the variability in human color perception.

33 Discussion

34 There are multiple ways to approach the problem of predicting visual perception from
 35 the sensory signal. The Bayesian approach described here is an example of the computa-
 36 tional approach as characterized most famously by Marr (1982). Other common
 37 approaches are the mechanistic approach and one I will term the piecework approach. In
 38 the mechanistic approach, parts of the model are thought of as abstractions of pieces in a
 39 real visual system. One understands color vision (or visual perception) by understanding
 40 the physiology that underlies it in the mammalian system. Typically, the foundation of
 41 mechanistic models is the responses of neurons in early visual areas (such as the retina,

1 lateral geniculate nucleus (LGN), and primary visual cortex) to simple, well-controlled
 2 visual stimuli whose dimensions can be well characterized. Mathematical approxima-
 3 tions of typical neural processes are used to guide model development (at least conceptu-
 4 ally; for an example, see ODOG—oriented difference of Gaussian filters—in Blakeslee
 5 and McCourt 1999). This approach has achieved remarkable success in predicting per-
 6 ception for certain types of scenes (e.g., with uniform illumination). However, it is unclear
 7 as yet whether it will generalize to more complicated scenes where the image data are less
 8 easily parameterized with respect to neural responses. One can think of this type of
 9 approach as a ground-up model that takes as input an idealized retinal image, and uses
 10 the early physiological treatment of the sensory signal as the “guessing rules” to solve the
 11 ambiguity in image formation.

12 A second approach, which I have termed *piecework*, is to first segment a scene (or an
 13 idealized retinal image) using a higher level representation of the image or heuristics and
 14 then apply segment-specific rules to solving sensory ambiguity. A scene could be divided
 15 into a region of low illumination or high illumination, or segregated into regions repre-
 16 senting different depths. An example of this is anchoring theory (Gilchrist et al. 1999).
 17 The Gestalt principles of perceptual organization can be considered part of this tradition.
 18 Theories like this can explain a number of perceptual phenomena (Gilchrist et al. 1999).
 19 One drawback to this type of approach is that it is usually post hoc, and it is not clear how
 20 a particular approach should generalize to novel images. As Weiss et al. (2002, 603) state
 21 with reference to the motion stimuli, “Because these rules are not formulated directly on
 22 image measurements, it is not clear how one should generalize them for application to
 23 arbitrary spatiotemporal stimuli.”

24 A third approach is computational. The idea here is to consider perception as an infor-
 25 mation processing task and to consider the optimal way to solve that task. This approach
 26 is agnostic as to physiological implementation. The particular computational approach
 27 described here is Bayesian, although some of the advantages described here accrue to
 28 any well-conceived computational approach. One advantage of most computational
 29 models is that they provide testable predictions. For example, most computational mod-
 30 els take as input some set of numbers characterizing a visual image, and yield as output
 31 another set of numbers describing the estimated characteristics of that scene. In theory, at
 32 least, these estimates can then be compared quantitatively to human perception. Unlike
 33 more qualitative theories of visual perception, this allows for interpretable evaluation of
 34 models.

35 In addition to the more general advantage of providing testable predictions, two more
 36 advantages accrue to a specifically Bayesian computational approach: (1) compared to
 37 other models, Bayesian models tend to be more easily generalizable; (2) Bayesian models
 38 require an explicit mathematical representation of the assumptions that go into every
 39 modeling approach. The “guessing rules” that must underlie every modeling approach
 40 (even if they remain unstated) are formulated explicitly as the priors.

41 In discussing the Bayesian approach, it is important to recognize that it is not a refuta-
 42 tion of the ideas underlying either the mechanistic approach or the *piecework* approach.
 43 In fact, many likelihood functions are based on the same building blocks that go into

1 mechanistic models. With regard to the piecework approach, one can think of the priors
 2 as a way of mathematically formulating heuristics or as an alternative description of
 3 Gestalt principles. All three approaches are complementary.

4 The Bayesian modeling approach is used in many different fields. In the end, Bayesian
 5 statistical theory provides an optimal estimate given a set of assumptions. Those assump-
 6 tions are mathematically formulated as the likelihood function, the prior, and the loss
 7 function. In the context of Bayesian modeling of color, the priors have been interpreted
 8 here as a formalization of the guessing rules used to resolve sensory ambiguity. The priors
 9 used in these models capture something interesting about the statistics of the natural
 10 world. The priors, thus framed, are meant to characterize the salient features of the world
 11 in which the human visual system evolved. However, any of these Bayesian models as
 12 constituted could be generalized to include a prior that is less evolutionary in nature. For
 13 example, priors could be modified to include such variables as the prevalence of a par-
 14 ticular stimulus within an experimental session. In the models presented here, the loss
 15 function was very simple and never invoked explicitly. However, the loss function could
 16 be modified to include the experimental cost or benefit of making different kinds of
 17 errors within an experiment. Manipulating the expected frequency of a stimulus and the
 18 reward associated with different patterns of responses have been shown to change behav-
 19 ioral responses (Hudson et al. 2007; Knill 2007). Bayesian modeling that incorporates
 20 such stimulus changes into the prior and such reward contingencies into the loss function
 21 has successfully explained behavioral responses to certain types of visual stimuli (Knill
 22 2007), although experiment by experiment priors and loss functions have not yet been
 23 applied to color perception.

24 The computational approach described here differs from the mechanistic approach in
 25 one fundamental way. Although the Bayesian approach can functionally solve the prob-
 26 lem of sensory ambiguity, it does not speak directly to the question of neural implemen-
 27 tation or processing. Should a Bayesian model perfectly describe perception, it would not
 28 constitute evidence that the brain has circuits devoted to multiplying probability distri-
 29 butions, or that quantities such as prior probabilities are represented explicitly at some
 30 neural locus (although some research has suggested this, see Ma et al. 2006). Of course,
 31 the models described here do incorporate knowledge of the human visual system in the
 32 likelihood. However, the Bayesian approach is best thought of as a way to articulate
 33 cogently the relationship between assumptions and results, and as a good way to frame a
 34 complicated problem.

35 Although the algorithms presented provide estimates of color appearance that are in
 36 broad agreement with human data, the agreement is not perfect. There are several possi-
 37 bilities for the discrepancy. To compute likelihood and prior probabilities in a timely
 38 fashion, convenient forms of probability distributions are sometimes used. In each model,
 39 choices are made for how to parameterize scene variables. For example, in the constancy
 40 model, the data are weights on basis functions that describe reflectance and illuminant. In
 41 the color appearance model, the data are expected isomerization rates of cones. Each of
 42 these parameterizations requires assumptions and these affect the results. However, in

1 the case of the likelihood, the data generation process and scene parameters are often well
 2 understood; for example, isomerization rates of cones have been measured, and the
 3 optics of the eye are well characterized (Wandell 1995; Wyszecki and Stiles 1982). Given
 4 that the likelihood function is usually well constrained, it is often the choice of the priors
 5 that determines the model estimates; thus, lack of agreement between model estimates
 6 and human data may lie with the choice of priors. In each model presented here, the pri-
 7 ors are highly simplified characterizations of the natural world. In many cases, they con-
 8 tain known errors that are tolerated for computational reasons. In fact, given the
 9 simplicity of the priors and the statistical complexity of images, the degree to which the
 10 models do explain human perception is somewhat surprising.

11 However, despite the simplifications and limitations described above, the Bayesian
 12 approach to characterizing visual perception and constancy is appealing on broad empir-
 13 ical, theoretical, and philosophical grounds.

14 Empirically, Bayesian estimates are in good agreement with human visual perception in
 15 many different domains. Here I have described in detail results from two models. Bayesian
 16 models can also account for the speed and direction of motion perception (Stocker and
 17 Simoncelli 2006), perceptual phenomena associated with vision at low-light levels
 18 (Manning and Brainard 2009), shape perception (Knill 2007), perceptual bistability (Van
 19 Ee et al. 2003), and Bayesian approaches are being applied to a host of perceptual phe-
 20 nomena (see Kersten and Yuille 2003; Knill and Richards 1996). Moreover, Bayesian
 21 models are typically more parsimonious than other models, requiring fewer parameters
 22 to describe human perception under a wide range of conditions.

23 Theoretically, Bayesian models are easily generalizable. To make predictions about
 24 more complex stimuli, it is only necessary to add more distributions to the likelihood and
 25 probability functions, rather than engaging in *de novo* model construction. This modu-
 26 larity is useful. Estimates of object properties can be compared quantitatively to human
 27 performance and the effect of each intuition instantiated in the prior can be measured.
 28 For example, in the Bayesian model of color constancy (Brainard et al. 2006), the initial
 29 model that drew on the measured daylight prior exhibited some notable failures to pre-
 30 dict human performance. Subsequently, Brainard et al. (2006) derived the prior that
 31 provided the best possible fit to the data. This prior was considerably broader than the
 32 daylight prior that was originally used. Given that the likelihood is well constrained, and
 33 the functional form of the prior is defined, the strategy of determining what prior param-
 34 eters best account for the data can provide insights into visual system processing (Stocker
 35 and Simoncelli 2006). The empirical success of Bayesian models does not require that the
 36 brain represent probabilities in the same way that the models do. However, if the priors
 37 that work best in different models all seem to share a critical feature (viz., representation
 38 of statistics of natural images), this may suggest that those statistics are relevant to the
 39 neural substrates underlying perception.

40 Finally, although Bayesian algorithms are themselves agnostic to philosophical ques-
 41 tions, an interested party might make some observations about the nature of visual per-
 42 ception from the assumptions that are required for Bayesian algorithms to make estimates

1 of color appearance that agree with human estimates of color appearance. Specifically, it
 2 is interesting to note how the Bayesian algorithms presented here predict both successes
 3 and failures of constancy (Brainard et al. 2006; Stocker and Simoncelli 2006; Weiss et al.
 4 2002). Given that the likelihood is well constrained, it is the parameters of the priors that
 5 control model success. In multiple cases, perceptual phenomena that have seemed to
 6 indicate flawed or suboptimal perception have been recast as the output of a rational
 7 perceptual system. The model that predicts color constancy also predicts failures of con-
 8 stancy when they occur (Brainard et al. 2006). The model that predicts the seemingly
 9 incomprehensible pattern of responses to very small spots of light also explains percep-
 10 tion of more typical color stimuli. A model that explains veridical speed perception in
 11 high-light conditions also predicts various motion illusions under low-light conditions
 12 (Weiss et al. 2002). The critical importance of the priors in predicting human perception
 13 in a wide range of contexts suggests three interrelated points.

14 First, when some property of a prior shows itself to be empirically useful in very differ-
 15 ent circumstances, the philosophical implications of that property are worth considering.
 16 Specifically, because the required priors in each of the presented models have the com-
 17 mon feature of capturing the statistics of natural images, a philosophical account of visu-
 18 al perception should take seriously the notion that the visual system is “designed” for
 19 veridical perception in environments considered important from an evolutionary point
 20 of view. An important goal of philosophical and psychological accounts of perception has
 21 been to find correspondence between parameters of physical objects (e.g., reflectance,
 22 spatial extent) and parameters of the relevant perceptual space (e.g., color, size). Illusions
 23 and failures of constancy are seen as obstacles to discovering this correspondence. Color
 24 has been seen as particularly puzzling because the relationship between physical param-
 25 eters is not related in an obvious way to perceptual dimensions. Taking priors, likelihood
 26 functions, and cost functions seriously means rethinking the notion that there exists a
 27 direct correspondence between some parameters that span a physical space (e.g., reflect-
 28 ance of an object) and some parameters that span a perceptual space (e.g., perceived
 29 color). Under this view, the visual system does not care about getting things right, *per se*.
 30 It cares about getting things right enough to survive. Veridicality is important in the envi-
 31 ronments in which veridicality would have been essential for an organism’s survival.
 32 Thus, the correspondence between physical properties of objects in the world and per-
 33 ception of those properties ought to be mediated both by the probability with which the
 34 properties occurred and the costs of getting those properties wrong.

35 It may seem troubling to abandon the notion of direct correspondence between
 36 the properties of objects and the properties of perception; after all, if object properties
 37 do not uniquely determine perceptual properties, and perceptual properties of a
 38 given object vary from scene to scene and from observer to observer, then deriving a
 39 principled account of perceptual properties may seem impossible. The appeal of the
 40 Bayesian approach is that it provides an empirical account of perception in a wide variety
 41 of circumstances that does not rely on hand-waving. Failures of constancy and visual
 42 illusions can be given a unified explanation and do not require an ecumenical approach
 43 to perception.

1 Second, if one accepts the Bayesian formulation that the optimal interpretation of a set
 2 of data (perception) is shaped by prior probabilities as well as the data themselves, then
 3 the set of properties it is possible to perceive veridically is constrained. There are states of
 4 the world that a Bayesian algorithm would predict will never be perceived veridically
 5 because they are considered too unlikely. For example, in the model of color constancy,
 6 some of the variability in constancy is explained by the degree to which the actual state of
 7 the world is an improbable state of the world (according to the prior). In the Bayesian
 8 formulation, because purple illumination is very unlikely, surfaces illuminated by purple
 9 light will be perceived as more purple than they actually are.

10 A third related point is that the Bayesian framework provides an empirically parsimo-
 11 nious and philosophically appealing account of both visual illusions (Geisler and Kersten
 12 2002) and variability in constancy (Brainard et al. 2006). One model containing one set
 13 of priors can predict both illusions and veridical perception; there is no need to think of
 14 illusions as errors or puzzles in a philosophical sense. Others have noted the importance
 15 of errors in understanding the human visual system (Brainard et al. 2006; Geisler and
 16 Kersten 2002; Gilchrist 2006). As Geisler and Kersten (2002, 508) noted when describing
 17 one Bayesian model, “These perceptual errors seem to reveal a rational (but automatic)
 18 perceptual system designed to correctly interpret the retinal images evoked by the world.”
 19 Thus, visual illusions and variability in constancy can be thought of as the output of a
 20 rational visual system rather than as epiphenomena of some strange kind.

21 The Bayesian approach suggests one possible way to frame the discussion of multiple
 22 judgments, although there is not yet empirical data to support this idea. The Bayesian
 23 approach suggests that to make an estimate of what object is in the world given the sen-
 24 sory signal, we combine the likelihood, the prior, and the cost function to determine what
 25 object was most probable. But what if the expected Bayes’ utility is multimodal; that is,
 26 what if two objects are both equally likely (or relatively so)?

27 Perhaps multiple judgments are possible only when the expected Bayes’ utility is mul-
 28 timodal. This multimodality could arise for at least two reasons: (1) The utility/cost func-
 29 tion could push you in one direction while the posterior pushed you in another. This is
 30 akin to saying that the visual system estimates that a surface is white, but an experimenter
 31 has said you will win a million dollars if you correctly identify a dark surface, and you will
 32 lose 10 cents if you misidentify a white surface. (2) The posterior itself could be multi-
 33 modal. This could happen if the likelihood pushes estimates in one direction while the
 34 prior pushes estimates in another direction. An example of this could be when a purple
 35 surface is presented under purple illumination. Depending on the formulation, the likeli-
 36 hood could be high for states of the world that include purple illumination, but the prior
 37 could be very low for those states. Thus, the posterior could have high probabilities for
 38 both purple illumination and also for daylight illumination.

39 I speculate that if the expected Bayes’ utility is not multimodal, then only one judgment
 40 is possible. Furthermore, I speculate that when expected Bayes’ utility is multimodal, two
 41 judgments are possible, and the different causes of multimodality implicate different
 42 kinds of judgments. When the multimodality occurs in the posterior, then both judg-
 43 ments are perceptual or apparent. That is, the book is experienced as being both white

1 and not-white. Alternatively, when multimodality arises from differential pulls between
 2 the cost function and the posterior, I propose that one judgment is perceptual (the left
 3 half of the book is darker) and the other is cognitive (but I know it must be painted the
 4 same as the right half of the book).

5 These ideas are entirely speculative; designing a Bayesian algorithm that is simple
 6 enough to generate this kind of multimodality but rich enough to suggest interesting
 7 psychophysical experiments is not a trivial endeavor, but one that could provide worth-
 8 while empirical predictions.

9 In summary, any account of visual perception must solve the computational and philo-
 10 sophical puzzles of sensory ambiguity. There are multiple ways to do so. Bayesian
 11 approaches, while not perfect, provide an intuitive, generalizable, and philosophically
 12 interesting solution to the problems of sensory ambiguity.

Plate 10 (see also Fig. 11.1) Illustration of sensory ambiguity. (© Maria Olkkonen, 2011, reproduced here with permission.)

Plate 11 (see also Fig. 11.2) Examples of four stimulus configurations viewed by human observers in Delahunt and Brainard (2004). Subjects adjusted a test patch at the location indicated by the black square until it appeared achromatic. (Reproduced from Brainard, David H., David R. Williams, and Heidi Hofer, Trichromatic reconstruction from the interleaved cone mosaic: Bayesian model and the color appearance of small spots, *Journal of Vision* 8(5): pp. 11–23 © 2008 Association for Research in Vision and Ophthalmology, with permission.)

Plate 12 (see also Fig. 11.3) Illustration of a small part of the photoreceptor mosaic for five subjects. Retinas were imaged using adaptive optics techniques described in Hofer et al. (2005a). (Reproduced from Brainard, David H., David R. Williams, and Heidi Hofer, Trichromatic reconstruction from the interleaved cone mosaic: Bayesian model and the color appearance of small spots, *Journal of Vision* 8(5): pp. 11–23 © 2008 Association for Research in Vision and Ophthalmology, with permission.)

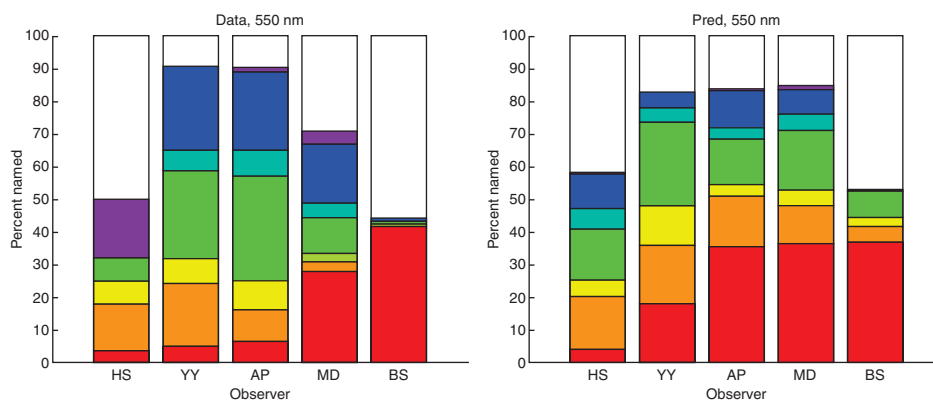

Plate 13 (see also Fig. 11.4) Actual (left) and predicted (right) color names for presentation of 550-nm spots. The observers' task was to report the color of each spot they judged nameable. The histogram shows the proportion of total presentations named the illustrated color. (Reproduced from Brainard, David H., David R. Williams, and Heidi Hofer, Trichromatic reconstruction from the interleaved cone mosaic: Bayesian model and the color appearance of small spots, *Journal of Vision* 8(5): pp. 11–23 © 2008 Association for Research in Vision and Ophthalmology, with permission.)
